

HOMO ERECTUS ON UNIFIED QUATERNARY PLATFORM OF INDIA AND CHINA.

ABSTRACT:

The Narmada Rift valley is conspicuous ENE-WSW to E-W trending prominent composite structural system across Indian sub-continent. It consists of various blocks which are dislocated and faulted along various faults and lineaments in space and time. The Narmada Rift System consists of various sub-basins like Hiran, Sher Shakkar, Dudhi, Tawa, which are minor basins are integrated and built part of main rift System. These sub-basins possess imprints of rifting and sinking events. These imprints are recorded in terms of manifestation and signature on landscape, drainage, of land form elements, present and paleo-meandering signature, river terraces, cut of meanders, paleo channels, scars, rock cut terraces, entrenchment and linear and curvilinear scars. These sub-basins have developed transverse to the main axis of Narmada rifting and had deep cut across the quaternary blanket. The evolution of Narmada graben is differential and asymmetrical with rifting and sinking valley floor. The Narmada basin contains fossiliferous Pliocene–Pleistocene volcanic fabrics, sediments and volcanic rocks which were occupied by early hominid populations. The Main Narmada rift is both symmetrical and asymmetrical in different segments along its length of about 1300 km. Several paleoanthropological localities, archeological sites ranging in age from the Pliocene–Pleistocene times were discovered within these basins. The discovery of Human Skull Homo erectus from boulder conglomerate bed of Hathnora formation Khan (1992) by Sonakia (1984) De Lumley, and Sonakia, (1985): in Sehore district M.P. India was first fossil skull of man from Indian sub-continent. It is correlated with Homo-erectus of China on Quaternary Platform is found to be the oldest homo-erectus in Asia Khan et.al (2013)

The known Pliocene–Pleistocene paleoanthropological localities have given us information about ancestors who were habitants and sparsely concentrated in the Narmada rift valley. This is not a coincidence, because the volcanic and tectonic activities that were responsible for the formation of the rift basins and formed the loci of Quaternary sedimentation & created ideal environments for the proliferation of life and the preservation of faunal and floral remains. The Quaternary volcanic eruption, ash fall, repeated tectonic dislocation and were responsible for the quick burial and preservation of fossils during diagenesis. The assemblages of sediments and granulometric parameters, diagenetic processes involving silicification, calcification, feldspathization, clay formation, and pedogenesis all played vital roles in fossil preservation in the sediments. The various rock fabrics, ash bed, paleo- sole inter bedded with the fossiliferous sediments also provide temporal information about geologic processes, faunal evolution, paleo-environment, and early hominid behavior and lithic technology. The skull cap of Narmada Man Homo erectus was found in Narmada Valley near village Hathnora (22° 52' N; 77° 52' E) in fossiliferous boulder conglomerate, in district Sehore, M.P., India. The skull cap is completely fossilized undistorted, renal vault nearly complete except few left supra-orbital and sutures are nicely preserved. The various morphological features and robust form of skull and excessive thickness of the bones indicate that it belongs to adult male individual (Sonakia, 1984). The discovery of skull cap of Homo erectus in fossiliferous boulder conglomerate in association of other mammalian

fossils is recorded in stratigraphic column of Quaternary deposits at the depth of 83 m, where estimated total thickness of deposits is about (325 m). This blanket consists of sediments of three domains viz. glacial, fluvio-glacial and fluvial, which were deposited in distinct environment during Pleistocene to Holocene time (Khan & Sonakia (1992), (Khan et.al. in press). The statistical analysis of sediments from these different domains in vertical column has been conducted to ascertain the environment of sedimentation and trace the breaks in climate (Khan et.al. in press). An attempt has been made for the first time Khan et.al (2013) to correlate the various stratigraphic columns of associated hominid fossils of Narmada valley (325 m) India and that of Luochuan sequence, (90-120 m) Chenjiawo (50 m) and Congwangling sequence (36 m) of China on unified Quaternary platform tied up and developed at mean sea level. The study revealed that the depth of occurrence of Narmada skull cap on unified Quaternary platform is about (83 m) as compared to that of Chenjiawo and Gongwangling of China which occur at very shallow depth of 38 and 26 m respectively. The estimated age of Narmada Man based on these parameters is about 1.38 m.y. (+), which is greater than Homo erectus of Chenjiawo 0.65 m.y. and Gongwangling 1.15 m.y. of China. An Zhisheng and Ho Chuan Kun (1989). On the merits of correlation of stratigraphic columns of Quaternary of Narmada, accumulation of sediment, rate of sedimentation, palaeo- environments,

lithostratigraphy and biostratigraphic position of boulder conglomerate in unified Quaternary Platform, author consider it as one of the earliest and oldest Homo erectus in Asia. Khan et al (2013). The study of morphometric parameters of skull cap of Narmada man and palaeo-environmental setting of Hominid locality in Narmada Rift System indicates that it belongs to an adult male individual and lived in dry cold and seasonally humid climate in Narmada Valley during middle Pleistocene time

1.00 Introduction

The Narmada river originates from the Amarkantak plateau of Satpura Range in Rewa at an elevation of about 1057 m (22° 40' - 81° 45') flows westerly course for about 1284 kms length across the middle of Indian subcontinent before entering Gulf of Cambay in the Arabian sea near Baroda in Gujarat state. It enters the fertile alluvial plain and passes through the gorge of about 19 kms long consisting of Marble rocks near Jabalpur. It then takes westerly turn through the alluvial tract, situated between the Satpura and Vindhyan hills. The river course of Narmada conspicuously straight and is controlled by ENE-WSW to E-W lineament, is bounded by Vindhyan in the north and Satpura in the south. The valley has maximum width of about 32 kms. The principal tributaries of Narmada River are Sher and Sakkar in Narsingpur, the Tawa and Ganjal in Hoshangabad, and Gaur in Jabalpur. They all originate from the Satpura hills to the south of the trunk channel. The only important tributary on the north is Hiran River, which emanates from the Vindhyan hills in Jabalpur district. Most of these tributaries have short and precipitous course after they debouch from the hills. The Quaternary tract of Narmada basin covers an area of about 12950 sq. km starting from west of Jabalpur (23° 07' 79° 53') to east of Harda (22° 29'; 76° 58') for a distance of about 320 km. It is found to be ideal locus of Quaternary sedimentation in Central India as witnessed by multi-cyclic sequence of Quaternary terraces in the valley. The general elevation of Narmada alluvial plain varies between 265.7 and 274.3m above the sea level. The general gradient of this plain in this stretch is about 1m /Km towards West.

HE-1 The Narmada Fossil is a part of a part of a skullcap; (bottom) its artificial reconstruction (Photographs Courtesy: Arun Sonakia) December 5, 1982. On the banks of the Narmada at Madhya Pradesh's Hathnora village, geologist Arun Sonakia stumbled upon what turned out to be the most tantalizing fossil discovery of a human ancestor. Narmada Human was the discovery of the century. Kids in our school learn about Java Man and Peking Man but hardly anyone knows about Narmada Human.

The discovery not only put India on the world fossil map, it proved the presence of early humans in the subcontinent and filled a void in our knowledge about human evolution, says D K Bhattacharya, former head of anthropology department at University of Delhi. "The discovery opened a new chapter in terms of hard evidence of evolution in south Asia," he says. "Unlike Africa, where stone tools were found along with human skeletons, all over India we were finding prehistoric stone tools, but there was no fossil evidence."

Narmada Human, initially named Narmada Man, belongs to the category of *Homo erectus*, preceding *Homo sapiens*, the modern human species. *Homo erectus* are believed to have inhabited the planet 1.8 million to 200,000 years ago. "On the basis of associated fauna, palaeomagnetic dating studies by the Geological Survey of India (GSI) and morphological features compared with other fossils of known antiquity, the Narmada fossil could be 500,000 to 600,000 years old," says Sonakia, now retired from GSI. The fossil could be of an individual aged between 25 and 30 years, he adds.

Antiquity of fossils has always been controversial. Some think the Narmada fossil may belong to the late *Homo erectus* category. Many believe the fossil could be of a female. "The evidence is not even a full skull. It is rather, a skullcap with a little bit of orbital roof," says Bhattacharya. The finding has been scientifically analyzed. "We think it represents a human form that had colonized India at least 400,000 years ago," he adds.

Homo erectus had successfully adapted to savannah grasslands, says Bhattacharya. They had domesticated fire, did group hunting and used stone tools. In French Riviera, at a site called Terra Amata, there is evidence of an artificial hut with hearths—and even a footprint—believed to be the handiwork of *Homo erectus* from 400,000 years ago. Surely, one fossil can never tell the full story. So, why don't we have more fossils from India?

In some regions presence of fossils depends on preservation conditions such as soil chemistry and erosion rates, says Parth Chauhan, research associate with US-based non-profit Stone Age Institute, and with the anthropology department at Indiana University, US. In other regions, either enough systematic survey has not been done or potential hominid fossil material has been overlooked. In India, palaeoanthropology or study of human origins is in a very neglected state, he says. Developmental projects such as dams on the Narmada, mining and oil drilling activities, intensive agriculture and population pressure have taken a

toll on fossil study. “Hundreds of palaeoanthropological and Stone Age sites are getting destroyed across the subcontinent,” says Chauhan.

Bhattacharya says India still follows the archaic 18th century mode of palaeontology. The country does not even have a national palaeontology institute. Guidance, experience and trained expertise are also lacking, says Chauhan. Palaeoanthropology is rarely practised in India in its pure form through multi-disciplinary approaches as in other regions such as Africa. Barring some exceptions, most studies in India have been non-systematic and not comprehensive, he says.

1.1 Previous work & Review of the literature:

Splishbury (1833) was first to initiate the paleontological study of Quaternary deposits of Narmada valley. Princep (1834) described the Splishbury collection, which now forms the part of fossil collection in British museum. Falconer (1859) and Ledekker (1880, 1882, 1884) have given the detail account of vertebrate fauna from Narmada valley. Theobald (1886) was first to study the Quaternary deposits of Narmada in Hoshangabad and surrounding area. He referred the quaternary deposits of Narmada of Pleistocene age. He divided these deposits in lower and upper Groups and reported an axe from reddish clays of the Upper Group. In the following year Late (1881) recorded a human cranium (transported), which was identified as Homo sapiens, supposed to have come from conglomerate bed of Lower Group. Unfortunately the cranium specimen was lost in the museum of the Asiatic society of Bengal, hence the find remained inconsequential. Pilgrim (1905) reported various stone implements and considered the deposits to be Pleistocene age. De Terra and De Cardian (1936), De Terra and Petterson (1939) correlated these deposits with the Pleistocene of Northern India. Broadly they agreed to the classification of Narmada in to lower and as opined by Theobald (1860). The Homo sapiens cranium, which Theobald thought, came from the conglomerate bed, according to them it could have come from a younger deposit. Khan (1984) carried out through detailed, geological, geomorphological and sedimentological studies and identified three prominent terraces in the Central sector of the Narmada. The alluvial deposits of the Narmada valley represent the thickest quaternary deposits in peninsular India. They contain the richest vertebrate fossil assemblage including only known Hominid fossil from the Indian sub-continent (Sonakia 1984). The boulder bed which yielded Hominid fossil first time reported for the first time to be of glacial & fluvial origin (Khan & Sonakia 1992). Beside occurrences of association of ash beds with fossiliferous boulder conglomerate (Khan & Rahate 1991) indicate some of the volcanic

source. It appears that close to the completion of cycle of deposition of the boulder bed there was powerful volcanic eruption and subsequent settling of the ash. The occurrences of association of two marked horizons at different levels further reveal the cyclic eruption and settling of volcanic matrix during sedimentation. Khan and Sonakia (1992) reported for the first time glacial and interglacial deposit in the Narmada valley, Central India which is represented by arid and humid cycles. The morpho and lithostratigraphy of Narmada valley described by Khan (1984), Khan & Benarjee (1984), Khan & Rahate (1990-91), Khan & Sonakia (1992), Khan et al (1991), Rahate & Khan (1985), Khan (1991), Khan & Sonakia (1992), Yadav & Khan (1996).

The Narmada valley forms a ENE-WSW lineament and Quaternary deposits in it are confined to trough like basin, with profound asymmetry in northern and southern valley walls. The Narmada valley in Peninsular India forms a prominent lineament with profound geomorphologic and geological asymmetry between the northern and southern valley walls, giving it a tectonic significance. The alluvial deposits of the Narmada valley represent the thickest Quaternary deposits in peninsular India. Beside association of fossils and tool assemblage and stone implements with Quaternary deposits of Narmada which are well described, quarries on various aspects on geology, geomorphology, sedimentology, provenance of sediments, stream kinetics, stratigraphy, chronology, tectonics, neotectonic, subsurface geometry, and overall model of Quaternary sedimentation of Narmada in faulted and sinking platform under structural riparian rift trench remained silent and unrevealed hidden miseries and needs attention. A lot of data has been generated on Narmada Valley Quaternary deposits during last 150 years. The different workers have studied the subject separately in the line of their specializations Roy, A.K. (1971) but there has been very little coordinated approach towards understanding and building up the Quaternary sedimentological history of the valley.

In the present work an attempt has been made for the first time to conduct detailed sedimentological studies with a objective to build-up and conceive the Quaternary sedimentological model with Environment of sedimentation of the Hominid locality Hathnora in Narmada valley. About 150 sediment sample were collected from surface and subsurface quaternary deposits and from ongoing drilling project logs upto 180 m below the ground surface and carried out detailed statistical analysis in the laboratory (Table No HE_1 to_3 & Table No QGMT_33 to_36. Plate No GH_3 to_7)

2.00 Quaternary Geology of Hominid Locality Hathnora

The Narmada valley forms a ENE-WSW lineament and Quaternary deposits in it are confined to trough like basin, with profound asymmetry in northern and southern valley walls. The Narmada valley in Peninsular India forms a prominent lineament with profound geomorphologic and geological asymmetry between the northern and southern valley walls, giving it a tectonic significance. The alluvial deposits of the Narmada valley represent the thickest Quaternary deposits in peninsular India. These sediments were deposited in faulted and sinking platform under structural riparian rift trench remained silent and unrevealed. The quaternary blanket of Narmada consists of sediments of various domain which were deposited in different environment in vertical chronology in faulted trough in time and space.

The statistical parameters viz MZ, STD, SKI, and KG of 150 sediment samples were computed from vertical column of 180 m of Quaternary blanket of Narmada. The synchronized study of these parameters revealed that the quaternary blanket consists of sediments of three domain exhibiting three distinct phases of sedimentation viz glacial, fluvio-glacial and fluvial. The study of statistical parameters and their binary relation distinctly display contrasting and relative heterogeneity in sediment characteristics throughout across the Quaternary blanket in Narmada valley. The study of sediments

display diagnostic characteristics of glacial, fluvio-glacial and fluvial environment at different depth and levels 000.m to 150, 150 to 350, and 350 to 550 m from glacial, fluvio-glacial fluvial, and fluvial deposit (150 samples). The critical analysis of these parameters exhibit sediment textural linkage to long evolution in glacial, fluvio-glacial and fluvial environment in time and space in increasing antiquity in the valley. The characteristics inherited by the sediments from pre-existing domain of sediments are glacial & terrestrial & environment. The diagenetic and diagnostic features; varying degrees of heterogeneity, sediment angularity roundness, degree of sorting indicate evolution and sedimentation of quaternary sediments in a high-energy turmoil glacial environment on tectonically dislocated and unstable platform. The sediments confined up to 150 m below ground level represent paleo fluvial domain of Narmada and represent multi cycle sedimentation under varying energy condition on oscillating platform. The vertical variation in increasing antiquity in textural parameters and distinct breaks at specific level identified indicate changes of environments of sedimentation in vertical columns from glacial at the bottom of valley trough subsequently followed by fluvio-glacial and further overlain by fluvial deposits which is related with change of climate and tectonic in watershed of Narmada

The binary relation of these parameters effectively used in differentiating and fencing the sediments of these domains and their environment of sedimentation in time and space. The binary plots of co-efficient of sorting v/s kurtosis and coefficient of sorting v/s mean diameter have been used as effective tool in delineating an area of occupation of glacial and its activity. The plots of skewness v/s mean diameter and kurtosis v/s mean diameter have also been found effective to some extent in delineating areas glacial and fluvial activity. The fluvio glacial sediments in all the above plots show most erratic behavior and are not to be bounded by any pair of parameters. But however, the plot kurtosis v/s skewness is positive to some extent in demarcating a flexible boundary between glacial and fluvio-glacial sediments.

In Homnid locality Hathnora the area is occupied by thick Quaternary sediments which are classified on the basis of statistical parameters. quartz grain morphology of sediments, quartz grain morphology of quartz grain of paleosol, heavy mineral assemblage, and ash bed sedimentary features and environments of sedimentation. The lowermost units (Boulder bed) is of glacio-fluvial origin (Khan et al 1991) whereas the rest of fluvial origin. The top four formations (Sohagpur, Shahganj, Hoshangabad and Janwasa) are classified based on morphostratigraphic state (NT_0 - NT_3), degree of oxidation, calcification and compaction. Janwasa formation comprises of sediments of active channel deposition and is the oldest three (Sohagpur, Shahganj, Hoshangabad formation) are related to older flood plains deposits of paleo-domain of Narmada and are grouped under older alluvium. Boulder conglomerate of fluvio-glacial origin is assigned an independent formation status based on distinct lithology and fossil assemblage. The sequence of Quaternary events and the history of sedimentation of Narmada indicate that the upper 70m to 90m of the Narmada alluvium was deposited in a single aggradation episode with minor pauses when dissection of the alluvium produced two terraces (NT_3 - NT_2). The sediments of this aggradation episode constitute three lithostratigraphic units viz. Boulder conglomerate, Sohagpur and Shahganj formation. The sediments of the alluvial phase are underlain by a boulder bed of glacio-fluvial origin. Thus, the fossiliferous boulder conglomerate, the basal unit of alluvium marks a disconformity between the lower glacial-boulder layer and upper fluvial sediments. The fossiliferous basal boulder conglomerate is being of middle Pleistocene age (Khan 1999). On the merits of detailed study of sediments Quaternary deposits of Narmada valley divide in to three distinct group viz. glacial, fluvio-glacial and fluvial; their age, litho constituents, environments of deposition and associated geomorphic elements are given in the Table I below:-

Table-I: Quaternary Formations of Narmada Valley

Age	Quaternary formations	Lithe constituents	Environments of Deposition	Associated geomorphic Phenomena
1	2.	3.	4.	5.
Recent	Younger Alluvium Fluvial terraces /fluvial deposit of present domain of Narmada	Reworked sediments, mostly rock gravel consisting boulder, cobble, pebble of quartzite, gneiss, granite, schist, basics, slate, phyllite, limestone & shale in a matrix of coarse to fine sand	Channel & flood plain environments	Point bars, channel bars, present day active flood plane and channel braids: fluvial terrace: NT-0.
Holocene	Fluvial terraces fluvial deposit s/ older alluvium 9 Sediment of paleo-domain of Narmada	Coarse gravel consisting of boulder, cobble, pebble, of quartzite gneiss granite, schist, phyllite, slate, fossiliferous limestone, shale & basic rocks in a matrix of coarse to fine sand.	Channel & flood plain environments	Fluvial terraces of Narmada NT-0 ₁ to NT-3.
Late Pleistocene	Fluvio-glacial deposits	Sub-angular to sub rounded boulder, cobble, pebble of quartzite, gneiss, granite schist with subordinate amount of limestone, slate, phyllite & basic rocks with coarse to fine sand & silt.	Fluvioglacial environments	Fluvio-glacial deposits "FGT"
Pleistocene	Glacial deposit	A heterogeneous mix of sub- angular to angular boulder and cobble of predominately gneiss, granite, schist, & quartzite with subordinate amount of slate phyllite and shale together with very fine sand, silt & clays.	Glacial environment	Glacial deposits "GT".

A brief description of above Quaternary deposits is given below:

2.1 Boulder Bed (Glacial/Fluvio-glacial deposits)

The glacial and fluvio-glacial deposits of Narmada unconformable over the Vindhyan and the basaltic Deccan Trap rocks. The sediments consist of a Heterogeneous assemblage of sub-angular to angular, sub-rounded, unsorted, unstratified rock fragments ranging from boulders to small pebbles, predominantly of quartzite, gneiss, sandstone, basalt, jasper, chert, gneiss, sandstone, basalt, chert, altered feldspar, ferruginous nodules, in a matrix of very coarse to very fine sand, silt and clay. These clastics are highly angular, generally poorly sorted and isotropically impregnated. Fine sediments comprise of reddish grayish and greenish sand with appreciable amount of mica flakes,

altered feldspar, brick-red and buff silt, greenish-brown silt and clay, and greenish, reddish and dark maroon hard and plastic

UNDER PEER REVIEW IN IJAR

clay. These fine sediments contain fairly good amount of ferruginous material, quartz, mica flakes and altered feldspar grain. Through these sediments are similar in composition to the other deposits of Narmada Valley, exhibit entirely different sedimentary pattern, sediment characters and mineral composition. These rock clastics are largely angular, very poorly sorted and demonstrate isotropic imbrications pattern in the valley. The sediments of glacial domain of Narmada occur between and average elevation of about 20-265 m above m.s.l. and were deposited in glacial environments during Pleistocene time. These deposits are concealed under boulder conglomerate in the valley.

2.2 Boulder Conglomerate (Fluvio-glacial deposits)

The Vindhyan Group of rocks and Deccan Trap in the Central sector of the Narmada Valley form the basement for the Quaternary deposits. The conglomerate bed that constituted the fossiliferous horizon of Narmada is sandwiched between older Alluvium and the glacio-fluvial boulder bed. This conglomerate bed is a very persistent marked horizon indicating a distance phase of sedimentation in the Narmada Valley. It is exposed in the bluff/scrap of Narmada around Sardar Nager, Hathnora, Surajgarh, Budhni, Hoshangabad, Khoksa, Tigharia, Demawar and Bhariya-Ghat at the base of terraces NT₂ (Khan, 1984). The measured thickness of the exposed boulder conglomerate varies from 1.5 to 6.5m but average 5m. The boulder conglomerate predominantly consists of sub-rounded to well rounded boulder, cobble and pebble of quartzite, gneiss, sandstone, basalt, agate, jasper, chert, chalcedony tightly cemented in a matrix of sand and silt. The finer sediments include different grade of sand and silt, brown and maroon in color often laminated and cross laminated. The boulder conglomerate is fossil and skull cap of early man *Homo erectus* (Sonakia, 1984).

The boulder conglomerate consists of three sub-litho units; each sub-unit characterized by distinct rock fragment shape, size, lithological abundance and allied sediment characters. The sub-units are composed of variable assemblage of quartzite, gneiss, basalt, sandstone, agate, jasper, chalcedony, chert, sand and silt (Khan 1992). These sub-litho units display facies variation in the valley and upper units grades into gritty sandstone upstream of Hathnora.

The basal unit of boulder conglomerate and is characterized by sub-rounded to rounded boulders cobbles, pebble of quartzite (38.50%), gneiss (18.50%) sandstone (14.50%), basalt (6.50%), agate and other rock fragments (3.50%). These clastic are tightly cemented in a reddish brown and maroon sand and silt which exhibit lamination, cross-lamination and cut and fill feature. It is capped by a pebbly layer containing vertebrate fossils and a human skull of early man (Sonakia, 1984). The average measured thickness of this layer is about 2.25m.

The middle sub-unit of boulder conglomerate characterized by an abundance of spherical, discoidal and bladed cobbles, pebbles of quartzite (31.50%), gneiss (14.00%), jasper (8.50%), sandstone (15.00%), basalt (10.50%), agate (12.50%), chert (6.50%) and other rock fragments chert (1.50%). These coarse clastic are tightly cemented by a deep brown and maroon sand, silt and clay. The finer clastics display sedimentary feature like lamination, cross-bedding load structure, small ripples and, cut and fill feature. Out of this sedimentary structure the cross bed units of boulder conglomerate vary from 5.15° and average about is 8.5°. The cross-beds average is often truncated by a pebbly layer at the top. This sub-unit contains mammalian fossil and some stone implements. The average measured thickness of these sub-units is about 2m. The upper sub-units of the boulder conglomerate. It consists of sub-rounded to well rounded pebble of quartz (23.50%), gneiss (11.50%), sandstone (14.50%), basalt (13.50%), agate (15.50%), jasper (11.50%), chert (8.00%) and

other rock fragments (2.00%). These clastics are cemented by grey and brownish sand and silt containing appreciable amount of calcareous matrix.

These deposits identified between an average elevations of 245 to 300 m above m.s.l. the basal unit of boulder conglomerate identified is marked at an elevation of about 268 m above m.s.l, exposed on the northern bank of Narmada around Hathnora (22° 52' N - 77° 52' E) at the depth of about 83 m in stratigraphic column of Quaternary sediments of Narmada. The boulder conglomerate is of middle Pleistocene age equivalent to Siwalik boulder conglomerate (India), Trinil bed of Java (Indonesia) and boulder conglomerate of Tapi (Khan). These deposits have yielded skull cap of early man, *Homo erectus Narmadensis* along with other mammalian fossils (Sonakia, 1984). The Ash bed of Quaternary age is recorded associated with these deposits around Timrawan upstream of Hathnora is of aeolian nature and perhaps indicates volcanic activity during middle Pleistocene time.

2.3 Floodplain deposit of paleo domain of Narmada (Fluvial deposit)

The older alluvium conformably overlies the boulder conglomerate and represents the flood-plain facies of palaeo-domain of the Narmada. The sediments of the facies predominantly consist of clay silt and sand, discontinuous nodules and plates. The beds are horizontal, exhibit upward fining sequence typical of fluvial deposits. The older alluvium of Narmada can be divided into three formations based on lithology, sediment assemblage, shape and size of rock clastics, relative disposition and diagnostic sedimentary characteristics. These formations are, viz. (i) Sohagpur, (ii) Shahganj, and (iii) Hoshangabad Formations respectively. These formations represent the sediments of the palaeo-domain of Narmada deposited in channel and flood plain environments during Upper Pleistocene times.

Sohagpur Formation: The lowest Sohagpur Formation is named after Sohagpur town. The unit occurs along the outer flanks of Narmada Valley bounded by Vindhya range to the north and Satpura to the south. It consists of sediments of paleo-domain of Narmada comparable with Sohagpur geomorphological surface (NT3). It is represented by a thick sequence of clay, silt-sand and rock gravels. The unit is divisible into three sub-litho unit. The basal sub-unit is chiefly red and brownish sand, silt, clay containing appreciable amount of cal matrix. The average measured thickness of this sub-unit is about 6.25m. The middle sub-unit consists of yellow and brownish silt, clay with subordinate sand and occasional rock gravel lenses. The average measured thickness of this sub-unit is about 5.50m. The upper sub-unit predominantly consist of compact yellow clay, silt and calcareous concretion. The average measured thickness of this sub-unit is about 3.25m. The Sohagpur formation is often associated with discontinuous and impersistent pebbly horizon containing well sorted polymodal gravel of quartzite, gneiss, basalt, agate, jasper and chert in the matrix of course to fine-sand. The gravel is generally discoidal, spherical and exhibits higher indices of sphericity and roundness indicating their derivation from distance and mixed provenance during sedimentation.

2.4 Shahganj Formation:

The Shahganj formation is named after Shahganj, where this formation is best developed. It forms litho-stratigraphic unit overlying boulder conglomerate and occupies large area in the central part of the valley. It is exposed in the bluff section of Narmada around Narayanpur, Sardarnagar, Hathnora, Shahganj and Hoshangabad. This formation is equivalent to the Shivpur formation described by Khan (1984) from the downstream of Hoshangabad. It consists of sediments of palaeo-domain of Narmada and is comparable of Shahganj surface (NT₂). It is represented by clay, silt, sand accompanied by inconsistent pebbly bed.

containing quartzite, gneiss, basalt, chart, agate. The average measured thickness of this formation is about 15m. These sediments constitution three units each characterized by distinct lithology, rock classics and diagnostic sediment characters.

The lower unit is predominantly composed of pinkish and brownish, silty clay association with cal-nodules, lime concretion and profused veinlets of calcareous matrix. The measured thickness of this unit is 5.50m. The middle units comprised of yellow clay, silt with inconsistent bands of pebbles of quartzite, basalt, chart, agate, in the matrix of coarse to fine sand. This unit is profusely calcareous due to lime concretion and veinlets of calc-matrix. It contains fossil and stone implements. The average measured thickness of this unit is 7.50m. The upper unit is represented by yellow and brownish hard compact clay, silt with kankar. It has developed transverse cracks which are occupied by the calc-matrix and kankar and is capped by black soil 2m in thickness consisting of clay and silt.

2.5 Hoshangabad Formation:

It is named after Hoshangabad where it is best developed. It is the younger formation of the Narmada and is represented by the flood plain facies. It forms a distinct morphostratigraphic unit, above the present day flood plain of the Hoshangabad surface (NT₁). It is crescent-shaped and is confined within the meander loop of the Narmada. This formation comprises three units. The basal unit predominantly consists of rock gravels of quartzite, gneiss, basalt and agate imbricated in the grayish sand and silt. The middle unit is represented by unconsolidated imbricated matrix of sand and silt supported by bimodally sorted gravel of quartzite, basalt, agate and chart. The upper unit contains yellowish and brownish silt and clay with occasional calcium concretion. It is capped by black soil. The measured thickness of the units is 6.5m, 5.00m and 3.5m respectively. The sediments of fluvial domain of Narmada identified between an elevations of 268 to 350 m above m.s.l. and were deposited in channel and flood plain environments during upper Pleistocene (Plate No QG_28 to _31 Plate No QG_50 to _51)

2.6 Younger Alluvium (Younger flood plain deposited)

The younger alluvium is represented by sediments of active flood plain, point bar and sand bar facies of present domain of Narmada and consist of unconsolidated imbricated, stratified, polymodal sorted rock-gravel supported by very coarse to very fine sand and is named as Janwasa formation, after the village Janwasa where it is best developed. The measured thickness in the valley is about 5m. (Plate No GH_3 to _7)

Quaternary tectonics, sedimentation and the paleontological and paleo-anthropological record in the Narmada Rift System in Narmada Rift system presence of the Katni Formation with angiosperm flora suggests that sedimentation continued during Mio-Pliocene in localized lakes. The relative disposition of such lakes and subsequent deformation and structural dislocation on oscillating valley platform clubbed with rifting and faulting during Quaternary period has shifted the site of the lake towards the present alluvium-covered area between Harda and Jabalpur as presumed: where as the present study of various aspects of Quaternary blanket in SONATA lineament ZONE revealed that quaternary sedimentation was a sequential and continuous process in rift valleys system from Mio-Pliocene Pleistocene time, has deposited complete sequence of glacial, fluvio-glacial lacustrine and fluvial deposits with changing environments and climate in time chronology. The present disposition of quaternary blankets in Son Narmada Tapti and Purna basin is due to post deposition Quaternary tectonics which is solely responsible for dislocation, faulting and shifting of different blocks and distorting quaternary blanket ecology in rift system. The occurrence of Boulder bed and Boulder Conglomerate in Son Narmada Tapti and Purna with similar rock assemblages and suites of rock fabrics, heavy mineral assemblages, quartz grain morphology in critical and crucial sections across the SONATA LINEAMENT ZONE strongly support tearing and rifting of quaternary blanket during late Pleistocene time. The presence of thick boulder bed in Harda inliers area, such as at Chandgarh and north east of Barwaha, boulder bed in confluence of Tapti and Waghur around Khadgaon in Tapti valley Khan et.al (1984) supports this assumption.

The Narmada Rift System provides a unique setting for Quaternary geological sedimentological, pedological, paleontological and archeological investigations which indicates human origins and evolution. Skeletal and cultural remains of hominids have been recovered from many locations within the basins. The important paleontological, paleoanthropological and archeological sites occur within the Narmada Rift System. The most of localities occur on the rift floor in between Jabalpur-Harda, in the east and Barwaha-Rajpipla in the west in the valley.

The present analysis is based on studies carried out during 1982-1992 over a decade, and tremendous data on various aspects was of Quaternary geology, sedimentology, pedology, archaeology, tectonic, neotectonic and other related studies were acquired and accrued from the ground by systematic field work, on official assignment as part of government duty. The virgin and previously unknown areas of the rift basins were studied and inventory of paleoanthropological and paleoanthropological resources were made. The survey indicated the potential of the Mio-Pliocene Pleistocene time and late and early Pleistocene Quaternary sediments of the Narmada Rift System for

paleoantological paleoanthropological research.

The remarkable preservation of faunal and floral remains in the Pliocene–Pleistocene sedimentary rocks was possible because of quick burial by sediments. Moreover, these source rocks of rift system the Quaternary sediments and interbedded tuffs provided the necessary chemical components for the preservation of the fossils during diagenesis. There is a strong link between these dynamic processes, rapid sediment deposition, and fossil preservation. The most important primary and contextual data (fossils and artifacts) were embedded and preserved in sedimentary deposits until the recent exposure by tectonic-driven erosional processes. The time-stratigraphic data obtained from tephra interbedded with fossiliferous Quaternary sedimentary deposits provided an important framework for the study of hominid origins, evolution, adaptations, and cultural changes. The paleoantological Paleo- anthropological information from these localities is remained closely associated with Quaternary sedimentary deposits boulder conglomerate and boulder bed often related to the trench Quaternary sedimentation, formation and development of rift and linear basin caused by repeated uplift, and the development of rift basins that began in the middle to late Pliocene and Pleistocene period. The unfortunate part of these deposits is that due repeated tectonic dislocation and faulting they are dislocated and distorted and at present are concealed under the thick pile of sediments of present and paleo domain of Narmada of late Pleistocene and Holocene time. These deposits do not provide adequate opportunity to researcher to study the human remain as postulated, except limited section where they are exposed.

In Narmada valley the most of the hominid remains and associated artifacts would have been found associated with Miocene Pliocene–Pleistocene sediments in increasing antiquity unfortunately same are not exposed due rift system and tectonic setting. In the rift system the type development of Quaternary blanket is confined between Jabalpur Harda which possess the complete sequence of all three domain in increasing antiquity from the bottom of the rift trench Boulder bed (glacial), Boulder conglomerate (fluvial-glacial) sediments of paleo-domain of Narmada (fluvial). The intense tectonic activities within the basins of the Narmada Rift System during the Neogene and Quaternary periods have destroyed fossil record except the fossiliferous horizons exposed in river sections. The erosional-sedimentary cycle has persisted in the rift valley environment for millions of years as a result of the interplay between depositional and erosional forces driven by tectonic processes; there are numerous gaps in the fossil record, particularly in the important time period between Mio-Pliocene Pleistocene times. It is pertinent to understand the origin of Hominid during the late Miocene, but it is difficult to disclose mysteries of human evolution in Narmada due to concealed nature of these deposits in rift system, however the complementary part of Tapti-Purna Quaternary blanket may be potential and possessive of human remain and should be studied to trace further the imprints of fossil man taking in to account of SONATA LINEAMENT ZONE as single ecosystem for evolution of man in Indian subcontinent. However, evidence of the effects of tectonics on fauna and flora are distinct

and its signatures on dislocation and concealing of fossiliferous horizons are uncontrolled and ill defined in the ecosystem in the valley during the Pliocene–Pleistocene periods. The boulder conglomerate which yielded the skull cap of *Homo erectus* in Narmada rift from Hathnora Sonakia (1984) remained only discovery of hominid fossil in last two and half decades due to concealed and hidden nature of Mio-Pliocene Pleistocene deposits in rift system and inconsistency in exposure of fossiliferous horizon due to faulting, dislocation and subsidence of Quaternary blanket of Narmada rift system.

It is specifically incorporated that the Boulder Conglomerate which is of fluvio-glacial origin and has yielded human skull from Sonakia (1982) Khan & Sonakia (1992) is exposed impermissibly in scarp section of Narmada at few places only. The type section of Boulder Bed and Boulder Conglomerate which are potential sediments of human remains of Pliocene Pleistocene time are hidden and concealed under sediments of present and paleo-domain of Narmada in the valley. The quaternary sequence and depth of occurrence of skull cap, rate of sedimentation of Hominid locality Hathnora (22°52'77°52') (325 m) India, has been correlated with the Quaternary of Luochuan (90-120 m) Chenjiawo (50 m) and Congwanling sequence (36 m) of China on unified Quaternary platform tied up and developed at mean sea level to ascertain the depth of occurrence and of age of skull cap of Narmada *Homo erectus* Sonakia (1984), at the depth of (83 m) Khan et al. (1992) indicates that the human skull *Homo erectus* of Narmada is oldest in Asia. (Plate No HE_9)

3.00 Human Remains of Narmada

In India, the Quaternary alluvial deposits of the Siwalik region, the peninsular river valleys, and certain cave deposits have been searched for the skeletal remains of early humans. Over a century ago, Theobald (1881) mentioned the discovery of a human fossil skull that was lost before being described, but Kennedy (1980) has observed that this was from Umhuta on the Koana and not from the Narmada Valley, as has been widely supposed. Dinobird, before and after his discovery of the *Homo erectus* specimens from Java, hypothesized that the Siwalik region of India might yield skeletal remains of Pleistocene hominids (Hrdlicka 1930:17), and Khatri (1961) described the remarkable suitability of the Narmada Valley as the locus of a flourishing Palaeolithic culture, remarking prophetically that “from this part of the valley (central part of the Narmada Valley) we expect to have one day the most cherished discovery of fossil man”.

As Research project of Geological Survey of India bio-stratigraphic study of the Pleistocene Narmada alluvium was taken up by Shri A. Sonakia in October 1982 in parts of Sehore & Hoshangabad district of M.P. The discovery of the skull cap of a hominid was made on December 5 of that year 1982 (Sonakia 1984). A press release was distributed by the Government of India on July 21 and 22, 1983.

Plate No HE-4 Figure 1.a, Narmada *Homo erectus* skull in situ in conglomerate bed. b, Narmada *Homo erectus* skull, after recovery from in situ position

right lateral view. The Hominid site is located near Hathnora, a village on the northern bank of the Narmada River, and 40 km northeast of Hoshangabad town in Madhya Pradesh state (22° 40' N:81° 40' E). The Hominid site embraces quaternary blanket which is about 18 m thick at Hathnora. The main Pleistocene and Holocene alluvial deposits are part of a trough of about 320 km in length between Jabalpur to the east in Harda to the west and 20-50 km in width. These deposits have brought to light one of the richest Pleistocene mammalian assemblages in India.

De Terra and Teilhard De Chardin (1936) has presented a generalized section through the Narmada Pleistocene alluvium in the Hoshangabad area which was sketchy with undefined boundaries of lith units of quaternary strata. The fossilized skull cap was recovered from its basal gravel-conglomerate bed, which was exposed as a 100-m x 17-m wide erosional platform. This bed is nearly 3m thick and it directly overlies the Deccan Trap basalts of Eocene age exposed in the river bed. The skull cap lay embedded in the gravel with its right temporal bone resting on the base of the deposit. The other well preserved mammalian skeletal remains, including *Bos namadicus*, *Stegodon ganessa*, *Stegodon insignis*, *Hippopotamus namadicus*, *Equus namadicus*, and *Cervus* sp., were found associated with the skull in the gravel conglomerate horizon. In the immediate area of occurrence of skull cap stone implements, including large and medium-sized hand axes, flakes, cleavers, and choppers made of compact quartzite. In addition, medium-sized flint and chert scrapers were present. These tools resemble those of an Acheulian Industry. The implements were embedded in the basal gravel layers.

The discovery of the Hathnora hominid hopes and prospects have definitely increased for more discoveries of skeletal remnants of primitive hominids in the geographic province that constitutes the Indian sub-continent. Twenty-two years have since elapsed after the Narmada *Homo erectus* skull was discovered at Hathnora in Sehore district of the central India State of Madhya Pradesh. Surveys have been vaguely and sporadically conducted, but still any authentically reported news is very much awaited. Most of the surveys have been just of prospecting type, like scanning the lithological units similar to that of Narmada gravels in the Narmada River channel and other alluvial deposits, but what is really called for is a systematic and logic based search by multidisciplinary faculties of academic and surveying organizations and institutions.

With the deep paucity of skeletal material, it is very difficult to evolve a model to exhibit true and absolutely flawless picture of human radiation. Then there has been another ambiguity that human evolution and radiation is being generally observed in isolation from other contemporary mammals that essentially formed an integral component of the food web. Secondly, entire mammal legacy in the peninsular India is looked up as totally descended from the Mio-Pliocene Siwaliks. Not only the peninsular Indian but furthermore the mammals of the Indonesian Archipelago have been described as very closely related to the Narmada Quaternary fauna. However, the story of continuity of primate legacy is full of spatial gaps and negative options. It is matter of debate that in spite of development of complete quaternary column and hospitability of sediment in rock basin and succession of sediment from Miocene Pliocene to Pleistocene Geoscientist, paleontologist and Anthropologist are failed to extract any further skeletal remains from Narmada valley.

The Narmada *Homo erectus* remains comprising fairly complete neuro-cranium have provided evidence of early human existence in peninsular India. For quite long, the Narmada Valley has yielded one of the richest collections of gradually evolving Pleistocene mammals in their stratigraphic disposition. The Narmada *Homo erectus* possesses some of the typical *Homo erectus* features based on both metrical and non-metrical features summarized by Andrews, viz., the very low disposition of maximum cranial breadth, flat and gently receding frontal, strong and bulging mastoid and supramastoid crests, opisthocranium coinciding withinion, pronounced post-orbital constriction, strong

supraorbital torus, flat parietal, low temporal squama, angularity between the axis of the petrous bone and the thick tympanic plate, the later being in coronal plane, the occipital bone, strong but abraded than capital torus, thick external and internal tables of skull wall, metopic prominence, a median keel in parietal junction area, flanked by parasagittal depressions, and a clearly brought out bregmatic depressions and a clearly brought out bregmatic eminence. Kennedy utilizing multivariate analysis and highlighting negative factors only, however, differ in taxonomic assignment and prefer to designate the Narmada cranium as 'archaic' *Homo sapiens*. Kennedy however, quote that "the Narmada calvaria is the only wellpreserved and authenticated discovery of a Middle Pleistocene fossil hominid recovered from the Indian sub-continent and its geographical mid-point situation between the east and relatively richer fossil hominid sites in far East and Southeast Asia, and in the Eurasian and African land masses afford it a unique place." The Narmada *Homo erectus* was excavated along with typical Middle Pleistocene fauna, like *Stegodon namadicus* and *Sus namadicus* in the gravel conglomerate layer in which it was found in situ just overlying the Matuyama-Brunhes palaeomagnetic reversal shown by deeply oxidized silt. This reversal is dated at 0.78 Ma.

Besides Since 1830s the Central Narmada Valley has yielded innumerable Paleolithic artifacts and Pleistocene mammalian fauna. 150 years later, the year 1984 saw a discovery of Middle Pleistocene hominine partial cranium (Sonakia, 1984), followed later by the discovery of two clavicles and a partial left 9th rib (Sankhyan, 1997a, 1997b, 2005) from a layer just above near the same site, Hathnora. These findings brought Central Narmada valley to the forefront of human evolution in South Asia and generated considerable debate on the taxonomic status of Narmada hominin. The partial cranium received greater attention from Lumley & Sonakia (1985), who conceived it as of an "evolved" *Homo erectus*, the stand more recently continued by another French scholar, Mallas (2009). This was followed by another study by Kennedy et al. (1991), who highlighted several advanced traits and therefore referred it, to an "archaic" *Homo sapiens*. Several scholars viewed the cranium in the same manner on different grounds (Badam et al., 1986; Sankhyan, 1999, 2006; Kennedy, 2000; Cameron, 2004). Of late, the terms "evolved" *Homo erectus* "archaic" or "archaic" *Homo sapiens* cladistically received different connotations, and therefore, Narmada partial cranium was referred to a much wider Old World species, *Homo heidelbergensis* (Kennedy, 2007; Athreya, 2007; Sankhyan, 2010).

Initially, the two clavicles and the rib fossils were thought to have been derived from the same cranially known Middle Pleistocene hominine on grounds of stratigraphic proximity and inferred female sex and similar estimated age at death (Sankhyan, 1999). But, they remained enigmatic mismatch (Pearson, 2000) to the cranium, and therefore were ignored by notable scholars like Kennedy (2000) in discussion on hominin evolution in Narmada valley. Of course, they do not corroborate in the estimated body dimensions of a single hominine, and appeared morphologically distinct (Sankhyan, 2007), and therefore open up a possibility of a hitherto unknown Pygmy-sized species or archaic population in Narmada valley (Sankhyan & Rao, 2007; Van Heteren & Sankhyan, 2009), strengthened by a recent study (Sankhyan, 2010).

The fossilized skull of Narmada *Homo erectus* was found embedded in a conglomerate bed in the Narmada valley of central India. This bed occurs at the basal part of a formation sandwiched between two other formations of 0.73 Ma and 74000 yrs BP. The conglomerate bed has also preserved fossils of *Hippopotamus namadicus*, *Equus namadicus*, *Stegodon namadicus*, *Sus namadicus*, etc. having Middle Pleistocene affinity. All these stratigraphic and palaeontological evidences point to a Middle Pleistocene age of the Narmada *Homo erectus*. A hundred years of investigation on human ancestry in India was rewarded in the year 1982 with the discovery by the first author of a skull cap of *Homo erectus* from the Quaternary alluvial deposits of the Narmada valley in central India¹. In its first report, a Middle Pleistocene age, was assigned to it based on a preliminary study of the associated

mammalian fossils. But being the only authentic record of *Homo erectus* from the Indian subcontinent, its precise taxonomic position and age is still under discussion amongst palaeoanthropologists and paleontologists the world over. Consequently upon the skull find the detailed investigation of vom of fossil, its lithostratigraphy, Khan & Sonakia (1991) sedimentology, Khan (2015) Quartz grain morphology sediment column, Khan (2014-15) Quartz grain morphology of pale-sole, Khan (2014-15) Heavy mineral assemblage Khan (in Press) tephrostratigraphy, Khan et al. (1991) Khan & Maria (1912) magnetostratigraphy, and bio-stratigraphy and correlation of sediment columns in travalee wise, inter valley wise and on unified Quaternary Platform Khan et al. (2012) focusing on hominid localities of China these deposits have thrown fresh light on the age of the Narmada *Homo erectus*. Discoveries of volcanic ash beds and palaeomagnetic reversal in these deposits for the first time for peninsular India are breakthroughs in fixing the chronologic position of the skull. Fresh data on the age of the Narmada *Homo erectus* are also available by additional finds of fossil mammals and a detailed taxonomic study along with a thorough review of some families of mammals.

The *Homo erectus* skull was discovered embedded (Figure 1) in a conglomerate bed within the Quaternary alluvial deposits of the Narmada Valley. Several lithostratigraphic classifications have been suggested for Quaternary deposits of Narmada (Table QG No--) The conglomerate bed designated as Hathnora Formation This formation has a 19 m thickness at its type section and a 50 m compiled thickness. This Hathnora Formation is sandwiched between two formations, the older one Boulder bed of glacial origin showing Matuyama reversed polarity chron³ (0.73Ma) and the younger one of fluvial origin with tephra layer equivalent to Toba ash^{4,5} of 74,000 yrs BP. Some upper layers of these Narmada Valley alluvial deposits have also been proved to be older than 25,000 yrs BP by ¹⁴C dating which represents youngest deposits of present domain of Narmada.

Mammalian fossils of the families Bovidae, Elephantidae, Hippopotamidae, Equidae, Stegodontidae and Cervidae were found associated with the Hominid skull. The Surajkund Formation, which has yielded the hominid skull, has also preserved fossils of Suidae and Canidae which play a significant role in biozonation. Two extinct species of Hippopotamidae, namely, *Hippopotamus namadicus* and *Hippopotamus palaeindicus* occur in successive biozones in the Narmada Valley Quaternary alluvium⁸. *H. namadicus* is associated with the *Homo erectus* skull. This *H. namadicus* stands in between the other two Indian species *H. sivalensis* and *H. palaeindicus* in skull characters, nature of incisors, etc.^{9, and 10}. While *H. sivalensis* is reported from the Lower Pleistocene Siwalik deposits, *H. palaeindicus* is reported from the adjacent Upper Pleistocene to Lower Holocene Son Valley deposits also¹¹. Thus *H. namadicus* occupies a position between Lower Pleistocene and Upper Pleistocene. Species of the Equidae family found associated with the Hominid skull is *Equus namadicus*. It is either closely related¹² to Lower Pleistocene *E. sivalensis* or inseparable¹³⁻¹⁵ from that. *E. namadicus* also shows resemblance to Late Villafranchian *E. stenonis* of Europe and Central China¹⁶. This *E. namadicus* was subsequently replaced by *E. hemionus khur* during the Upper Pleistocene. A preliminary study indicated the presence of *Stegodon ganesa* associated with the Hominid skull¹. Further study, however, shows that these specimens do not preserve all diagnostic characters of *S. ganesa* and should better be assigned to *Stegodon* sp. A new species *Stegodon namadicus* with all diagnostic characters is also reported from the Narmada valley¹⁷. This species shows close affinity to Middle Pleistocene *S. orientalis* of South East Asia. Fossils of Suidae, on the other hand, were not recorded during excavation of the hominid skull. However, a fair number of specimens of fossil Suidae, *Sus namadicus* have been reported from the Quaternary alluvial deposits of the Narmada valley elsewhere. Later a fragmentary RM³ (A993, GSI, Nagpur) of this species has been collected from the same locality and same litho-unit which has yielded the Hominid skull. *Sus namadicus* shows affinity to Lower Pleistocene Siwalik *Sus falconeri*; the species is also reported from the Upper Pleistocene Kurnool Cave deposits¹⁸. *S. namadicus* possesses similar characters to Middle Pleistocene Chou-Ken-Tien form *Sus*

lydekkeri¹⁹. A single specimen (GSI Type No. 20425) of fossilized mandible of *Cuonaplinus* has been collected²⁰ from the litho-unit which has preserved the Hominid skull. The specimen showing M_3 absent and M_2 much reduced is somewhat intermediate between Middle Pleistocene European *C. a. priscus* and *C. a. fossilis*²¹. Though slightly larger, the Narmada form is also comparable to Middle Pleistocene Chinese *C. a. antiquus*^{22,23}.

Most common fossils in the Narmada valley are of Bovidae. Major members of this family, namely, *Bos namadicus* and *Bubalus palaeindicus* are reported to range from Middle Pleistocene to Lower Holocene. However, during the last two decades, a large number of collections of fossil Bovidae have been made which deserves a thorough review to make this prolific family more useful for precise biozonation. The other dominant member, *Elephas namadicus* is also considered to be of Middle Pleistocene to Lower Holocene age. But this form possibly includes two²⁴ or three²⁵ species or subspecies. On the other hand, it is again suggested that European *E. antiquus* and some Japanese forms belong to *E. namadicus*²⁶. These controversies are to be resolved to understand the role of this form in biozonation. Another family, Cervidae is not very abundant in Narmada valley. An up-to-date review work or even a proper taxonomic description is lacking for this family and thus its due significance in biozonation is yet to be recognized.

Fossils belonging to Hippopotamidae, Equidae, Stegodontidae, Suidae and Canidae are mainly relied upon for biozonation of the Narmada deposits. Fossils of these families collected along with the *Homo erectus* skull or from the same geological horizons containing the skull point to a Middle Pleistocene (in all probability its lower horizon) age of the Narmada *Homo erectus*. Studies on lithostratigraphy, magnetostratigraphy and tephrostratigraphy reveal that Narmada *Homo erectus* is from a bed just above a formation of 0.73 Ma and at least 19 m below a layer of 74,000 BP. The discovery of Indian *Homo erectus* bridges the gap between African *H. erectus* in the west and Chinese and Javan *H. erectus* in the east and south east respectively. There is a general consensus of opinion that Afro-Asian *H. erectus* ranges in age from Lower Pleistocene to Middle Pleistocene. Indian *H. erectus* falls within this range. Arun Sonakia* and S. Biswas

The geographically nearest *H. sapiens* that have been studied by Wakankar (personal communication) are from the well-known UNESCO Heritage caves of Bhimbetka, located barely 40 km northwest of the Hathnora *Homo erectus* site. The Vidhyan caves, rock shelters complex, well known for rock paintings, have also yielded bones of 10,000-12,000-year-old *Homo sapiens* with highly evolved features in a dorsally enlarged neuro-cranium, although there are innumerable caves in the low-dipping Vindhyan quartzite strata comprising the Vindhya mountain range that runs very close to the Narmada River channel on its northern side. The Bhimbetka complex is however much different from other rock shelters and since there is practically no stratified cave deposit of prominence, the chances of getting human or other cave dwelling animals are very meager. However, the thick pile of debris, just in front of these rock shelters, appears to be a potential ground for locating remnants of possible inhabitants.

The artifact sites in the sub-continent are numerous, but if we take into account the human skeletal remains, the geographically next location is that of Sarai Nahar Rai and Mahadaha remains of the Pratapgarh district of Uttar Pradesh. These remains were dug up accidentally during construction of irrigation canals. A large number of basal Holocene human remains with modern features have been systematically excavated here by Allahabad University scholars. Still older or contemporary could be a mandible from the later Pleistocene Mogasarayanigondi cave deposits in Kurnool district, of Andhra Pradesh with broad retro molar area and large mental foramen. This individual appears to be an aging adult surviving in a hibernating environment. In an overall granitic terrain in the southern peninsula, very thin veneer of alluvium is observed.

Sankhyan (2007) from Anthropological survey of India described two new hominine fossils from Netankheri upstream of Hathnora in the Central Narmada valley. They include a partial left humeral diaphysis NTK-F-02-07 (Figure 1) and a distal shaft fragment of the left femur NTK-F-07-05 (Figure 2), housed at Kolkata in the Palaeoanthropology Repository of the Anthropological Survey of India. These were derived from two different stratigraphic levels of a new fossil locality, Netankheri, located about 3 km upstream of Hathnora, along the northern bank of River Narmada (**Figures 3 and 4**). Sankhyan et.al (2012) have brought to light two more hominine fossils a humerus and a femur from a new locality, Netankheri. The femur is derived from the Middle Pleistocene stratigraphic horizon as the Hathnora skullcap, and shares similar “archaic” mosaic morphology of *Homo heidelbergensis*, also attested by new bio-stratigraphic and Paleolithic data. The humerus is derived from the pre-YTA (~75 Kya) Upper Pleistocene strata in association with unique fossilized bone artifacts and documents the early emergence of anatomically modern *Homo sapiens* in South Asia

.4.00 QUATERNARY COLOUMNS & CORRELATION OF HOMO ERECTUS OF NARMADA INDIA WITH HOMOERUCTUS OF CHINA

The skull cap of Narmada Man *Homo erectus* was found in Narmada Valley near village Hathnora (22° 52' N; 77° 52' E) in fossiliferous boulder conglomerate, in district Sehore, M.P., India. The skull cap is completely fossilized undistorted, renal vault nearly complete except few left Supra-orbital and statures are nicely preserved. The various morphological features and robust form of skull and excessive thickness of the bones indicate that it belongs to adult male individual (Sonakia, 1984).

The discovery of skull cap of *Homo erectus* in fossiliferous boulder conglomerate in association of other mammalian fossil is recorded in stratigraphic column of Quaternary deposits at the depth of 83 m, where estimated total thickness of deposits is about (325 m). This blanket consists of sediments of three domains viz. glacial, fluvio-glacial and fluvial, which were deposited in distinct environment during Pleistocene to Holocene time (Khan & Sonakia (1992), (Khan et.al. in press). The statistical analysis of sediments from these different domains in vertical column has been conducted to ascertain the environment of sedimentation and trace the breaks in climate (Khan et.al. in press). In present paper an attempt has been made for the first time to correlate the various stratigraphic columns of associated hominid fossils of Narmada valley (325 m) India and that of Luochuan sequence (90-120 m) Chenjiawo (50m) and Congwangling sequence (36m) of China on unified Quaternary platform tied up and developed at mean sea level. The study revealed that the depth of occurrence of Narmada skull cap on unified Quaternary platform is about (83 m) as compared to that of Chenjiawo and Gongwangling of China which occur at very shallow depth of 38 and 26 m respectively. The estimated age of Narmada Man based on these parameters is about 1.38 m.y. (+), which is greater than *Homo erectus* of Chenjiawo 0.65 m.y. and Gongwangling 1.15 m.y. of China An Zhisheng and Ho Chuan Kun (1989). On the merits of correlation of stratigraphic columns of Quaternary of Narmada, accumulation of sediment, rate of sedimentation, palaeo-environments, lithostratigraphy and biostratigraphic position of boulder conglomerate in unified Quaternary Platform, author consider it as one of the earliest and oldest *Homo erectus* in Asia.

The study of morphometric parameters of skull cap of Narmada man and palaeo-environmental setting of Hominid locality indicates that it belongs to an adult male individual and lived in dry cold and seasonally humid climate in Narmada Valley during upper segment of lower to middle Pleistocene time. Key words: Ash beds, Boulder conglomerate, fluvial, fluvial-glacial, glacial, *Homo erectus*, Pleistocene, quaternary, quaternary platform and sedimentation.

The Narmada river originates from the Amarkantak plateau of Satpura Ranges in Rewa at an elevation of about 1057 m (22° 40' - 81° 45'), flows westerly course for about 1284 kms length across the middle of Indian subcontinent before entering Gulf of Cambay in the Arabian Sea near Baroda in Gujarat state. It enters the fertile alluvial plain and passes through the deep gorge of about 19 kms long consisting of Marble rocks near Jabalpur. It then takes westerly turn through the alluvial tract, situated between the Satpura and Vindhyan hills. The river course of Narmada conspicuously straight and is controlled by ENE-WSW to E-W lineament, is bounded by Vindhyan in the north and Satpura in the south. The valley has maximum width of about 32 kms.

The Quaternary tract of Narmada basin covers an area of about 12950 sq. km starting from west of Jabalpur (23° 07' 79° 53') to east of Handia (22° 29'; 76° 58') for a distance of about 320 km. It is found to be ideal locus of Quaternary sedimentation in Central India as witnessed by multi-cyclic sequence of Quaternary terraces in the valley. The total estimated thickness of Quaternary sediments in the central sector of Narmada is about 325 m. In present paper attempt has been for the first time to correlate the Quaternary sequence of Hominid locality Hathnora (22° 52' 77° 52') (325 m) India, with that of Luochuan (90-120 m) Chenjiawo (50 m) and Congwanling sequence (36 m) of China on unified coded model of Quaternary platform tied up and developed at mean sea level to ascertain the depth of occurrence and age of skull cap of Narmada Homo erectus Sonakia (1984) which has been recovered from boulder conglomerate in the valley of Narmada. (Plate No HE_9)

Splishbury (1833) was first to initiate the paleontological study of Quaternary deposits of Narmada valley. Princep (1832) described the Splishbury collection, which now forms the part of fossil collection in British museum. Falconer (1859) and Yedekker (1880, 1882, 1884) have given the detail account of vertebrate fauna from Narmada valley. Theobald (1860, 1881) was first to study the Quaternary deposits of Narmada in Hoshangabad and surrounding area. He referred the Quaternary deposits of Narmada is of Pleistocene age. He divided these deposits in lower and upper Groups and reported an axe from reddish clays of the Upper Group. In the following year Late (1881) recorded a human cranium (transported), which was identified as Homo sapien, supposed to have come from conglomerate bed of Lower Group. Unfortunately the cranium specimen was lost in the museum of the Asiatic society of Bengal, hence the find remained inconsequential. Pilgrim (1905) reported various stone implements and considered the deposits to be Pleistocene age. De Terra and De Cardian (1936), De Terra and Petterson (1939) correlated these deposits with the Pleistocene of Northern India. Broadly they agreed to the classification of Narmada in to lower and upper Group as opined by Theobald (1860). The Homo sapien cranium, which Theobald thought, came from the conglomerate bed, according to them it could have come from a younger deposit. They collected many Paleolithic tools, and stone implements but they were unsuccessful in coming across any mammalian fossil. Based on fossil assemblage and stone implements they compared the Quaternary of Narmada with those of Middle Pleistocene of North Western India characterized by fauna Elephas antiquus (mammalian). Hoojier (1963) and Khatri (1980) studied various paleontological aspects of Quaternary deposits of Narmada valley. Triparthi (1968) compared and correlated the Quaternary deposits of Godavari Valley with the sediments of Narmada Alluvium, on the basis of fossil assemblage and stone implements. According to him the Narmada fauna was equivalent to older alluvium fauna of Indo-Gangetic plain and slightly older than that of Kurnool cave deposits. Roy, A.K. (1971), studied various aspects of ground water of Narmada valley. Gupta (1974) studied geological and geomorphologic aspects of parts of Narmada valley. Adyalkar (1975) studied paleogeography of Narmada in relevance to ground water potential. Biswas and Dassarma. (1981) Badam (1979) and Dassarma (1979) studied the fossil assemblage of Quaternary strata of Narmada valley.

Khan(1984)carriedout detailedgeological,geomorphological andsedimentologicalstudies and identified three prominent terraces in the Central sector of the Narmada. (Khan Sonakia 1992), studied Quaternary deposit in vertical column in relevance to occurrence of Human Skull and reported glacial and fluvio- glacial deposit in Narmada valley for the first time. The boulder bed which yielded Hominid fossil for thefirst time reported to be of glacial - fluvial origin (Khan & Sonakia 1992). Beside occurrences of association of ash beds with fossileferous boulder conglomerate (Khan & Rahate 1991) indicates some distant volcanic source.

Khan and Sonakia (1992) reported for the first time glacial and interglacial deposit in the Narmada valley, Central India which is represented by arid and humid cycles. Magneto-statigraphic studies are being carried out by (Rao, et.al 1997). The lithostratigraphyof Narmada valley describedby Khan(1984), Khan & Benarjee (1984), Khan & Rahate (1990-91), Khan & Sonakia (1992), Khanet al (1991), Rahate & Khan (1985), Khan (1991), Khan & Sonakia (1992), Yadav & Khan (1996).

Thefirst author was associated with Narmada valleyproject as official assignment from 1982 to 1992 on the merits data base data synthesis and results obtainedheattemptedto build up the lithostratigraphy of sediment,to conceive the three dimensional model of Quaternary platform of Narmada with special reference to concealed and hidden fossiliferous boulder conglomerate to correlate the Quaternary of Hominidlocality Hathnora (22°52'77°52')(325 m) India, with thatofLuochuan (90-120 m) Chenjiawo(50m) andCongwanling sequence (36 m) of China on unifiedQuaternary platform. (Table No 1)

5.00 QuaternarySequenceof Narmada India

In Narmada Valley the area around Hominid locality of Hathnora is occupied by thick and multiple sequences of Quaternary sediments. Based on study of statistical parameters of sediment their deviation and breaks in vertical stratigraphic column between 00.00 to 260 m below the ground level indicate that the sediments consist of three domains viz. glacial, fluvio-glacialandfluvial.(Khanet.alinpress)Thestudyof these concealed sediments, their sedimentary environments and sedimentation and correlation both in vertical and horizontal columnsindicatesthatthelowermostunits,Boulderbed(20to260m.belowgroundlevel)isofglacialorigin,whereasthefossiliferousbedBoulderconglomerate (260to278m. abovem.s.l.)isoffluvio-glacialandtopfourformationsinincreasingantiquitySohagpur, Shahganj, Hoshangabad and Janwasa(278 to 350m. above m.s.l.) are offluvial origin and represent the complete sequence of Quaternary sedimentation in Central India. The Janwasa formationcomprisesofsedimentsofactivechanneldepositwhereastheolderthree(Sohagpur, Shahganj, Hoshangabad formation) are related to older flood plains deposits of paleo-do-main of Narmada and are grouped under older alluvium. Boulder conglomerate of fluvio-glacial origin is assigned an independent formational status. Khan & Sonakia (1992). (Table No HE _1 to _3)

.6.00 Indian Homo Erectus and evolution

(22°-52'N-77°52'-E)

The skull cap of Narmada man Homo erectus Narmadanesis was found in near village Hathnora (22 ° 52" N; 77 ° 52" E) in fossiliferous boulder conglomerate, (Sonakia, 1984)at an elevation of about 268m above the m.s.l. and at the depth of about 83m in Central Narmada Valley. These deposits are underlain by glacial deposits and overlain by fluvial deposits of palaeo-domain of Narmada. The Quaternary sequence of Hathnora is described by Khan & Sonakia (1992).

The boulder conglomerate at Hominid locality Hathnora consist of stratified hard compact basal unit comprising of rock fragments of different shape and size of granite, quartzite, sandstone, agate, chalcedony, chart, basalt and calcareous nodules tightly cemented in the matrix of brown, red and grayish sand and silt. These rock clastics constitute various sub-litho units and are supported by grey and brownish, cross bedded sand. The sub-litho units consists of mostly pebble supported horizons which contains vertebrate fossils, stone implements, like chopper, scraper hand axes and core flakes mostly of quartzite, flint, chalcedony and quartzite.

A mandible of Lantian hominid at Chenjiawo (China) was found in paleosol (S6) and at the depth of 38 m in the loess deposits. A Zhisehng et. al. (1989). Assuming a roughly uniform accumulation rate of sedimentation in the line of Ma. et. al. (1978) estimation of age, the date of the Lantian mandible at Chanjiawo is computed to be about 0.65 m. m.y.r. Ho-chuan at the depth of 26 m which were deposited in typical fluvial environments. In view of recovery of skull cap of *Homo erectus* (Narmada Man) from older deposits and from deeper level (83 m.) as compared to Chinese Hominid, the claim of Lantian Hominid of Congwangling (1.15 m.y.r.) after A Zhisehng et. al. (1989) needs re-evaluation of reassessment of its age.

The rock basin of Narmada is occupied by the Quaternary sediments of three domains viz. glacial, fluvio-glacial and fluvial which were deposited in distinct environments during Quaternary time. The glacial deposit comprised of thick pile of sediments occupied base of rock basin and was deposited by glacial activities in dry and cold climatic condition during early Pleistocene time. The boulder conglomerate constitute fossiliferous horizon of Narmada, deposited in fluvio-glacial environments (interglacial). It is a marker horizon of Quaternary sedimentation in Narmada Valley and as well in Central India its disposition and relation with other deposits in the valley, indicates a significant change in regional climate from cold dry to warm and humid, during which the sediment were re-worked from glacial front intermittently and deposited in the valley over a very long time. The skull cap of *Homo erectus* (Narmada Man) and other fauna recorded along with calc-nodules within the boulder conglomerate; suggest that warm climatic phase prevailed long time. The Lantian hominid cranium at Gongwangling was found in silty loess at the depth of about 26 m. and in Luochuan standard sequence the fossil bearing stratum un-doubted to the middle part of silty loess L-15 which at Luochuan was dated to be 1.09 to 1.20 m.y.r. The hominid fossil and associated faunas were discovered in the middle part of silty layer; the age of the fossils at Gongwangling can be pinpointed narrowly to 1.15 m.y.r. This dates differs from the earliest (0.75-0.80 m.y.r.) of Ma. et. al. (1978) and from 1 m.y.r. estimate of Cheng et. al. (1978). The Lantian fossil hominid at Gongwangling is considered as earliest *Homo erectus* in China. Ho Chuan Kun (1986).

In India Narmada basin considering the one of a main loci of Quaternary sedimentation, and assuming the uniform accumulation rate of sediment in the basin in the line of Ma. et. al. (1978) Yobin Sun & Zhisheng, An (2005) and comparing the Narmada sequence of Quaternary deposit (325 m.) with those of Luochuan standard sequence of Chenjiawo and Congwangling sequence of China. The skull cap of *Homo erectus* (Narmada Man) recovered from the boulder conglomerate of fluvio-glacial origin in middle part of Quaternary column from deep level of Narmada, at the depth of 83 m. above glacial deposits, in association of ash bed, as compared to Chenjiawo Hominid from interbedded sequence of paleo sols loess and silty loess at the depth of 38 m. and Congwangling 26 m. from paleo sols which are younger than Narmada deposits. The Narmada skull cap of *Homo erectus* which is recovered from the top of basal unit of boulder conglomerate at the depth of 83 m. (278 m. above m.s.l.) is estimated to be of upper segment of lower Pleistocene age. It is older than the *Homo erectus* of Chenjiawo, Congwangling of China which were recovered from paleosol and loess deposit at the depth of 38 and 26 m. The Quaternary sequence of Narmada (325 m.) as compared to Luochuan (136 m.) sections of China on unified Quaternary platform is older and represents the complete and type sequence of

Quaternary sedimentation in Central India. The occurrence of skull cap of early man at the depth of 83 m. in basal unit of boulder conglomerate of fluvio-glacial origin in Narmada Valley is one of the earliest and oldest *Homo erectus* in Asia. (Plate No HE_9 Plate No GH_3 to_7)

7.00 Hominid Locality LuochuanChina

In China the study of human origins and evolution, now known as palaeoanthropology, began with the discovery of a worn and fossilized hominid molar tooth at Zhoukoudian, 48 kmsouthwest of Beijing, by the Austrian geologist Otto Zdansky in 1923. Subsequent work at the cave deposit between 1927 and 1937 by European, North American, and Chinese scholars, including Johan Anderson, recovered a large number of hominid fossils and associated cultural remains Wu, M.(1980,1983, 1987), Wu, R. (1988), Wu, R et.al (1982,1983,1987), Wu,X&Poirier(1995),Wu,Xet.al(1966),Wu,X.&WL;1985, Wu,X. & Zhang, Z (1985) Weidenreich, F, (1936) Weidenreich, F, (1937b). Up until 1995, information on Middle Pleistocene China was restricted by the minimal amount of publication in languages other than Chinese, the research opportunities and interests of western palaeoanthropologists and the limited travel opportunities available to the Chinese scientific community. This situation as dramatically changed in 1995 with the publication of Wu and Poirier's Human evolution in China.(Wu,X & Poirier 1995), it has provided for the first time the detailed morphological, metrical descriptions and associated quaternary sediments of all of the major Chinese Pleistocene hominids in a single volume.

Author availing the opportunity of availability of Chinese literature and data of Hominid localities has studied and correlated the Quaternary sequence of Hainan of Narmada India with Luochuan Quaternary sequence of China taking all salient and diagnostic elements and parameters on unified Quaternary platform for correlation for the first time.

7.1.0 Luochuan sequence

The Luochuan is considered to be standard and type sequence of Quaternary deposits of China. A Zhisheng et. al. (1989). The Chenjiawo and Congwanling hominoid sequence have compared with the sequence of Luochuan and Narmada for the purpose of building the lithostratigraphy and magneto-stratigraphy and ultimately assigning the age to hominid fossils. The Luochuan Sequence is multiple sequence of red clay, silty loess, loess and paleosol constituting differential litho units of variable thickness. The red clay with loess constitute the base of these deposits whereas the two sub-litho units of silty loess (L₉ & L₁₅) are located within the sequence at depth of 60 and 80 m interbedded within paleosol and loess units. There are fourteen (14) sub-litho units of loess litho bedded with paleosol at an average depth of 0-75m; besides three weathered paleosol ws-1 to ws-3 between 90 to 120 m. The paleosol units though form thinner horizons as compared to loess sediments but their frequency of occurrence and cumulative thickness constitute the major part of Luochuan deposits.

These deposits are associated with fairly good amount of calc- matrix and depict multiple cyclic sequences. Though the thickness of various sub-litho units decreases towards top and average total thickness of these deposits is about 130 m. These deposits are of riverine in origin as evident by the study of litho-logs after An Zhisheng (1989).

7.2.00 Chenjiawo Sequence

The Chenjiawo (34.15.N, 115.00 E) is located in a small tributary of Xiehu. Though the stream is of subsequent nature, but contribute appreciable sediment load from higher reaches and have entrenched the quaternary blanket of Bahe river, the trunk stream Xiehu

drains north easterly across the Central China. The Chenjiawao deposits consist of inter bedded complex sequence of palaeosole, loess, silty loess with sand and rock gravels at the base. It comprises of nineteen (19) sub-units of palaeosole, twelve (12) sub-units of loess, two (2) sub-units of silty loess with one (1) sub-unit of sand with sand gravel at the base. The total thickness of these deposits is 50 m. The sediments are fairly calcified depict cyclic sedimentation and upward fining sequence typical of basin deposits. An Zhisheng (1989).

The Mandible Hominid of Chenjiawo was found in palaeosole (S6) at the depth of 38 m. assuming roughly, uniform accumulation rate of soil loess couplets within Brunhes portion of this section, the date of Lantian mandible at Chenjiawo is estimated to be 0.65 myr. This is in line of Ma et al. An Zhisheng (1989). The Chenjiawo deposits besides Lantian Hominid consist of other final assemblage and are of middle Pleistocene age.

7.3.00 Congwangling Sequence

In China early human fossil were found either at various horizons of loess or in fluvial deposits of river basin. The fluvial deposit represents the former valley floor of river system and sediment of old flood plain facies which are often covered under loess of different ages. The Congwangling (34° 11' 15" N-109° 30' 00") is situated in main Bahe river valley north east of Lantian in Shaanxi province of Central China. The *Homo erectus* is recovered from loess deposit (9th layer of loess sequence) which is situated near Gongwangling village. The Gongwangling (Lantian) cranial fragments were discovered east of Lantian, in 1964 by a team from the Institute of Vertebrate Paleontology and Paleoanthropology, Beijing (Wu and Poirier, 1995; Wu et al., 1966). The first hominid fossil to be found was an isolated maxillary molar and several months later this was followed by large cranial vault fragments. A large quantity of mammalian faunal material was also recovered from the site. A dominance of tropical and subtropical species has suggested a warmer climate Gu, & Jablonski, (1989); Qi, (1989). An et al., (1990); An and Ho, 1989; Wu et al., (1989) have described the various artifacts from the Gongwangling site as being primarily cores with five flakes and four scrapers.

The Gongwangling hominid skeletal materials were first described in detail by (Woo, 1965). A detailed English language discussion of Gongwangling can be found in Beijing (Wu and Poirier, 1995). The human fossils (PA 1051-6) include a complete frontal, large part of the parietals, most of the right temporal, part of the left and right nasals, and a large section of the right maxilla with associated second and third molars, and part of the left maxilla. Features suggestive of *Homo erectus* are most apparent in the frontal bone which is broad, receding and have a robust supraorbital torus. There is marked postorbital constriction and no sulcus between the torus and frontal squama. Cranial vault bones are also relatively thickened certainly compared with *Homo erectus* from Zhoukoudian. In terms of geological age and sequence of early man in China in chronological order is: Gongwangling *Homo erectus*-Yuanmou *Homo erectus*-Beijing *Homo erectus* (or Chenjiawo *Homo erectus*-Hexian *Homo erectus*)-Dali Man (and Dingchun Man). It is evident that the Gongwangling Lantian Man is the earliest Quaternary human fossil so far found in China. (Plate No HE_9)

8.00.00 Conclusion

The skull cap of Narmada man *Homo erectus* Narmadensis was found in near village Hathnora (22° 52' N; 77° 52' E) district Sehore, M.P., India in fossiliferous boulder conglomerate. It is recovered in stratigraphic column of Quaternary deposits at the depth of 83 m in of Narmada valley, where estimated total thickness of deposits is about (325m). This blanket of sediments consist of three domains viz. glacial, fluvio-glacial and fluvial, which were deposited in distinct environment during Pleistocene to Holocene time (Khan & Sonakia 1992). The Skull Cap is completely fossilized undistorted, cranial vault nearly complete except few left supra-orbital sutures which are nicely preserved. The various

morphological features and robust form of skull and excessive thickness of the bones indicate that it belongs to an adult male individual (Sonakia, 1984). The discovery of Skull Cap of *Homo erectus* in fossiliferous boulder conglomerate in association of other mammalian fossils is recorded at the depth of 83 m; in the Quaternary is estimated to be about 1.38 m.y.r. (+) in age and can be considered as the oldest *Homo erectus* in Asia.

The estimation is based on study of fossils assemblage, association of ash beds, paleo soles, tephra bed in boulder conglomerate; palaeo environments, lithostratigraphic and biostratigraphic position of boulder conglomerate, depth of occurrence of skull cap (83 m.) and rate of accumulation of sediment in basin and position of fossil yielding horizon (330 m above m.s.l.), association of tephra beds, palaeo-sole, palaeo-environments, glacial and interglacial activities, in Central India during Quaternary time. The estimated age of Narmada Man is about 1.38 m.y.r. (+), which is greater than *Homo erectus* of Chenjiawo 0.65 m.y. and Gongwangling man of China 1.15 m.y. Ho Chuan Kun (1988), which occurs at the shallower depth of 38 and 26 m respectively in stratigraphic column of unified Quaternary platform as compared to Narmada Man.

The study of morphometric parameters of skull cap of Narmada man and palaeo-environmental setting of Hominid locality, indicate that it belongs to an adult male individual and lived in dry cold and seasonally humid climate during upper segment of lower to middle Pleistocene time. The Boulder Conglomerate which is a marker horizon in Quaternary deposits of Narmada is of fluvio-glacial origin and has yielded human skull from Sonakia (1982) Khan & Sonakia (1992) is exposed impermissibly in scarp section of Narmada at few places only. The type section of Boulder Bed and Boulder Conglomerate which are potential sediments of human remains of Pliocene Pleistocene time is hidden and concealed under sediments of present and paleo- domain of Narmada in the valley. The quaternary sequence and depth of occurrence of skull cap, rate of sedimentation of Hominid locality Hathnora (22°52'77°52') (325 m) India, has been correlated with the Quaternary of Luochuan (90-120 m) Chenjiawo (50m) and Congwanling sequence (36 m) of China on unified Quaternary platform tied up and developed at mean sea level to ascertain the depth of occurrence and age of skull cap of Narmada *Homo erectus* Sonakia (1984), occurs at the depth of (83m) Khan et al. (1983) indicate that the human skull *Homo erectus* of Narmada is oldest in Asia.

TableNo.1: STRATIGRAPHY OF QUATERNARY DEPOSIT OF NARMADA

Age	Nasrullahganj-HardaSection	Yathmore-HoshangabadSection	Amabalpur-NarsinghpurSection	Lithology	Environmentof sedimentation	Geomorphismsurface(River-terraces)&Land-formselementsHoshangabad-HathanicSection	
Recent	Janwas a/Indra/ Kolarof Ambaformation	Youngeralluvium(Youngerflood plain deposit)	Janwas formation	Fluvial sediment in the present domain of Narmada	Reworked sediment viz boulders, cobbles, pebbles of quartzite gneiss, basalt, jasper, agate, sand stone, laterite chert, with coarse to fine sand	channel and flood plain environment (flood plain point bars and channel bar facies) channel and flood plain environment (flood plain facies of palaeodomain) channel and flood plain environment (flood plain facies of palaeodomain)	Narmada terrace To point bar, sand bar channel bar , river braids
Holocene to upper Pleistocene	Demawar Formation	Older Alluvium	Hoshangabad Formation	Upper fluvial deposit of Narmada	predominantly well rounded boulders, cobbles, pebbles of quartzite gneiss, basalt, sand stone, agate, chert, chalcedony, laterite in the matrix of coarse fine sand silt & clay	channel and flood plain environment (flood plain facies of palaeodomain of Narmada) channel and flood plain environment (flood plain facies of Palaeodomain of Narmada)	Narmada terrace (NT1) Hasangabad surface (15m)
	Shivpur Formation		Shahganj Formation	Middle fluvial deposit of Narmada	predominantly boulders, cobbles, pebbles of gneiss, basalt, sand stone, agate, chert, chalcedony, laterite in the matrix of coarse of fine sand silt clay and sand predominantly boulders		Narmada terrace (NT2) Shaganj surface (16m)
	Nasrullahganj Formation		Sohagpur Formation	Lower fluvial deposit of Narmada	cobbles, pebbles of quartzite gneiss, basalt, sand stone, agate, chert, chalcedony, zeolite with clay silt and subordinate amount of sand disconformity		Narmada terrace (NT3) Sohagpur surface (15m)

middle pleistocene	Boulder conglomerate	Boulder conglomerate	Hatnora formation	Boulder conglomerate	predominantly sub rounded to rounded boulders, cobbles, pebbles of quartzite, gneiss, lime stone, sandstone, basalt, agate, chert, tightly cemented sand and silt disconformity	channel and flood plain environment (flood plain facies of palaeo domain of Narmada)	Rock cut terraces relict platforms and benches (5m)
Pleistocene	Boulder Bed / Glacial / Fluvio-glacial deposit	Boulder bed (glacial - fluvial)	Glacial / fluvio-glacial	Boulder bed / Glacial / fluvio-glacial deposit	Predominantly sub angular to sub rounded boulders, cobbles, pebbles of quartzite, gneiss, basalt, sandstone, with very coarse to very fine sand, silt and clay. Unconformity	Glacial / Fluvio-glacial environment (sediments of Glacial / Fluvio-glacial facies)	Valley fill sediments deposited by glacial / fluvio-glacial activities
